## Abstract

Marine sediments are a primary reservoir for the long-term storage of organic matter, and the rate of burial and oxidation of this sedimentary organic material help to regulate both atmospheric oxygen and carbon dioxide concentrations. To evaluate the impact of circulating basement fluid on the preservation of deeply buried organic carbon, sedimentary profiles of dissolved and particulate organic carbon (DOC and POC) near the sediment/base-ment interface were obtained from sediment coring at Site U1363 during Integrated Ocean Drilling Program Expedition 327. Sedimentary DOC increased from 0.25 mM at 1 m below the sea-water/sediment interface to a maximum of 0.86 mM at mid-depth (8–11 meters below seafloor [mbsf]), before subsequently decreasing to a minimum of 0.10 mM at the sediment/base-ment interface (222.7 mbsf). Thus, the oceanic basement appears to be a net sink for sedimentary DOC. Sedimentary DOC and alkalinity profiles were similar and inversely mirror those of sulfate, suggesting that the buildup of DOC in sediment pore water is related to re-mineralization of sedimentary POC. The sedimentary POC content at Site U1363 ranged from 47 to 391 µmol-C/g, with  $\delta^{13}\text{C}$  values from  $-25.3\text{\textperthousand}$  to  $-22.4\text{\textperthousand}$ . The total particulate nitrogen (PN) content ranged from 4.1 to 32.9 µmol-N/g, with  $\delta^{15}\text{N}$  values from  $1.8\text{\textperthousand}$  to  $7.2\text{\textperthousand}$  and a POC:PN ratio of  $12 \pm 2$  ( $n = 54$ ). No depth-specific systematic variations in POC, PN, POC:PN ratio,  $\delta^{13}\text{C}$ -POC or  $\delta^{15}\text{N}$ -PN were detected, and no significant correlations between sedimentary DOC and POC concentrations were observed.

## Introduction

Marine sediments are the primary long-term reservoir for organic matter (Emerson and Hedges, 1988), and the rates of burial and oxidation of sedimentary organic matter significantly contribute to regulating Earth's atmospheric oxygen and carbon dioxide concentrations (Holland, 1984; Holland et al., 1986; Berner, 1990). Buried particulate organic matter (POM) in the sediment is mobilized to inorganic compounds such as carbon dioxide and ammonium by aerobic and anaerobic respiration and to dissolved organic matter (DOM) by processes including microbial hydrolysis and anoxic fermentation (Laanbroek et al., 1982; Capone and Klein, 1988; Arnosti et al., 1994; Arnosti, 1995; Fenchel et al., 1998; Burdige, 2002, 2006). An imbalance between the produc-

tion and consumption of DOM results in dissolved organic carbon (DOC) concentrations in the surface sediments typically an order of magnitude higher than those in the overlying seawater (e.g., Alperin et al., 1994, 1999; Burdige et al., 1999; Papadimitriou et al., 2002). As a result, the flux of DOC from marine sediments to overlying seawater is roughly equivalent to that of riverine input and is a net loss of carbon from sediments to the water column (Burdige et al., 1992, 1999).

In contrast to the numerous DOC profiles published from surficial (<1 m) marine sediments (e.g., Krom and Sholkovitz, 1977; Burdige et al., 1992, 1999; Alperin et al., 1994, 1999; Burdige and Homstead, 1994; Burdige and Zheng, 1998; Burdige, 2002, 2006), only a few studies have examined pore water DOC concentrations within profiles extending to greater sediment depths (Michaelis et al., 1982; Egeberg and Abdulla, 1990; Seifert et al., 1990; Wefer et al., 1998; Simoneit and Sparrow, 2002; Heuer et al., 2009). Although the DOC concentrations within surficial sediments generally increase exponentially with increasing depth from the seawater/sediment interface until reaching an asymptotic maximum, DOC concentrations within deep sediment pore water generally do not demonstrate such systematic variation with depth. At some locations, depth profiles of DOC concentrations are similar to concurrently measured total particulate organic carbon and inorganic carbon profiles (Simoneit and Sparrow, 2002), whereas at other locations significant increases in DOC concentrations have been observed at greater depths due to hydrothermal activity from below (Simoneit and Sparrow, 2002).

The lack of a predictable pattern in deep sediment DOC profiles suggests that the deep DOC cycle may be more complicated than that occurring within surficial sediments. It is also not clear if the impact of hydrothermal activity always results in an increase in sediment pore water DOC concentrations. The fact that DOC concentrations in warm (65°C) basaltic rock basement hydrothermal fluids are lower than those in the bottom seawater (Lang et al., 2006; Lin et al., 2012) suggests that hydrothermally heated basement fluids can be a sink for deep sedimentary DOC (Lin et al., 2012) that may cause sedimentary pore water DOC concentrations to decrease with depth.

Particulate organic matter in deep-sea sediments acts as an important energy source for a diverse array of microbial metabolisms, including aerobic and anaerobic organotrophy using nitrate or sulfate as electron acceptors (Laanbroek et al., 1982; Capone and Klein, 1988; Fenchel et al., 1998). Major electron acceptors in deep sediments, such as oxygen, nitrate, and sul-

fate, originate from bottom seawater, and the penetration depths of these electron acceptors vary based on their concentrations in overlying bottom seawater, the sedimentation rate, and reactivity of POM (e.g., D'Hondt et al., 2002, 2004; Hartnett and Devol, 2003; Fischer et al., 2009). On the Washington Margin and eastern flank of the Juan de Fuca Ridge in the northeastern Pacific Ocean, sediment pore water oxygen and nitrate is exhausted at a few centimeters below the seafloor (Hartnett and Devol, 2003), and sulfate is significantly depleted relative to seawater at several tens of meters below the seafloor (Elderfield et al., 1999; Wheat et al., 2013). However, below the region of sulfate depletion, sulfate concentrations increase toward the sediment/basement interface due to the supply of sulfate from basement fluids (Elderfield et al., 1999; Wheat et al., 2013). The supply of electron acceptors from the deep basement into the sediment has been suggested to support microbial metabolism within the deep-sediment biosphere (D'Hondt et al., 2004; Engelen et al., 2008). In addition, Grizzly Bare outcrop on the eastern flank of Juan de Fuca Ridge provides a conduit for bottom seawater to recharge and mix with older and more reacted (i.e., anoxic) basement fluids (Fisher et al., 2003; Hutnak et al., 2006; Wheat et al., 2013) and provides additional electron acceptors to basement fluids and subsequently into deep sediments.

Although terrigenous organic matter discharged to the ocean is generally thought to be efficiently remineralized (Keil et al., 1997; Galy et al., 2008), on the eastern flank of Juan de Fuca Ridge an unusually high amount of terrigenous-derived organic matter has accumulated in the deep sediments near the sediment/basement interface (Prahl et al., 1994; Hedges et al., 1999; Dickens et al., 2006). This unique setting provides additional value to the study of terrigenous carbon preservation and degradation. This study provides DOC and POM (carbon, nitrogen, and isotopic composition) profiles at locations where the impact of hydrothermal circulation in basaltic basement on deep sedimentary organic biogeochemistry can be investigated.

## Methods and materials

### Sample collection and processing

Samples used for this study were from sediment cores taken from Integrated Ocean Drilling Program (IODP) Holes U1363G, U1363F, U1363B, and U1363C/D located on the slope of Grizzly Bare outcrop on the eastern flank of Juan de Fuca Ridge (Table T1; Fig. F1). The sediment/basement interface at these holes are 17, 35, 57, and 231 meters below seafloor (mbsf), respectively (see the “Site U1363”

chapter [Expedition 327 Scientists, 2011b]). Details of whole sediment and sediment pore water sampling are described previously (see the “**Methods**” chapter [Expedition 327 Scientists, 2011a]; Wheat et al., 2013). Briefly, sediment cores were collected using advanced piston coring (APC or “H” shown in Table T2) and extended core barrel (XCB or “X” shown in Table T2) systems on the R/V *JOIDES Resolution*. Once shipboard, roughly 10–40 cm of the whole-round sediment section was placed in a nitrogen-filled glove bag, and the outside 0.5 cm of the sediment core was carefully scraped using a polytetrafluoroethylene-coated spatula in order to remove potential contaminants, leaving a ~5.8 cm diameter core. The remaining sediment (~238–1030 cm<sup>3</sup>) was pressed using a titanium squeezer and hydraulic press piston to extract sediment pore water. The resulting pore water was then passed through a pre-washed Whatman Number 1 qualitative filter paper above a titanium screen and collected in a combusted (550°C; 5 h) glass syringe, before being filtered through a prerinse (50 mL deionized water) 0.45 µm pore-sized polysulfone membrane filter (Supor, Pall Corporation) and collected in an acid-cleaned and combusted glass scintillation vial. The pore water samples were kept frozen at -20°C until subsequently thawed on shore for analysis. Two blank samples that were collected by passing deionized water through the squeezer and filter series have DOC concentrations of 0.016 and 0.028 mM using the method described below. These blank values are an order of magnitude lower than the DOC in environmental pore water measured in the current study.

Sections of sediment after pore water extraction were carefully wrapped in combusted aluminum foil and frozen at -80°C shipboard. In a shore-based laboratory, ~5 g of frozen whole sediment from each sample was subsampled with a clean stainless steel spatula. The whole sediment subsamples were subsequently placed in combusted glass scintillation vials, loosely covered with combusted aluminum foil, and dried in an oven at 60°C. The dried sediment was powdered with a clean ceramic mortar for subsequent analysis as described below.

### Pore water-dissolved organic carbon

Sedimentary pore water DOC concentrations were measured by high-temperature combustion using a Shimadzu TOC-VCSH analyzer. The combustion temperature was set at 720°C to ensure complete oxidation of organic matter. Samples were acidified to pH <2 by the addition of 45 µL of 2 M HCl to 3 mL samples. No acid contamination was observed based on monitoring the DOC value of low-carbon deionized water. Samples were purged with nitrogen gas

within the autosampler syringe for 2 min in order to remove inorganic carbon. An injection volume of 150 µL was used, with five or six injections per sample. The reproducibility between replicate injections was <1 µM. Analytical reference materials (ARM) supplied by Dr. Dennis Hansell (RSMAS, University of Miami) were measured before, between, and after analysis of environmental samples (Sharp et al., 2002; Dickson et al., 2007). At least one ARM was measured every five samples. The average measured concentration of the ARM was 42 ± 2 µM (*n* = 44); the reported value was 41–43 µM. Our detection limit for DOC concentrations was ~2 µM.

### Sediment

Whole sediment samples were analyzed for concentration and isotopic composition of total carbon, organic carbon, and total nitrogen using an elemental combustion system (Costech ECS 4010) connected inline to an isotope-ratio mass spectrometer (Thermo Finnigan Delta XP). The amount of powdered sediment used for the analyses was optimized to provide sufficient carbon and nitrogen for isotopic composition analysis and varied between 26 and 425 mg. A subset of samples was acidified by fuming with concentrated HCl (Hedges and Stern, 1984) in order to remove inorganic carbon and quantify the particulate organic carbon (POC) content. Acid fuming did not remove inorganic nitrogen, resulting in insignificant differences between whole and acid-fumed total particulate nitrogen (PN) concentrations. Calibration for C and N concentration was performed by running reference materials with the environmental samples. The isotopic compositions of carbon and nitrogen are reported as δ values (e.g., δ<sup>13</sup>C and δ<sup>15</sup>N) expressed in permil (‰):

$$\delta = [(R_{\text{sample}}/R_{\text{standard}}) - 1] \times 1000,$$

where *R* is the <sup>13</sup>C/<sup>12</sup>C or <sup>15</sup>N/<sup>14</sup>N ratio. The standards for carbon and nitrogen isotopic composition are Vienna PeeDee belemnite (NBS 19) and air, respectively (Coplen et al., 1992; Coplen, 1994).

## Results

The concentrations of DOC in sediment pore water at Site U1363 ranged from 0.10 to 0.86 mM (Fig. F2; Table T2). For comparison, similar measurements from Ocean Drilling Program Hole 856 located at Middle Valley, also on the eastern flank of Juan de Fuca Ridge, ranged from 0.01 to 7.14 mM (Simoneit and Sparrow, 2002). The lowest sedimentary DOC concentration was observed near the sediment/base-ment interface of Hole U1363D, but the concentra-

tion was still nearly an order of magnitude higher than that in basement fluid collected by the IODP CORK in Hole U1301A, 55 km north of Site U1363 (0.10 versus 0.012 mM; Lin et al., 2012). It should be noted that the overall procedural blank for the measurement of DOC in basement fluid and bottom seawater was only 0.002 mM. In Hole U1363G, the sedimentary DOC concentration was 0.25 mM in near-surface sediment pore water collected from a sediment core depth of 1.4 mbsf, which is significantly higher than was found in background bottom seawater from this region (0.039 mM; Lin et al., 2012). Depth profiles of DOC concentrations at Site U1363 show a mid-depth (8–11 mbsf) maximum, unlike those from Middle Valley (Simoneit and Sparrow, 2002), which showed an increase toward the basement.

Interestingly, the depth profiles of DOC concentration parallel those of alkalinity and appeared to inversely mirror depth profiles of sulfate concentration (Fig. F2), suggesting that the buildup of DOC in sediment pore water might be related to remineralization of sedimentary POM. The correlation between sulfate and DOC concentration was high and indicated that ~0.09 mM of DOC was added to the pore water with every 1 mM of sulfate removed (Fig. F3). Similarly, ~0.07 mM of DOC was added to pore water with an increase of 1 meq/L of alkalinity (i.e., ~1 mM increase of bicarbonate; Fig. F3). However, no significant correlation was found between DOC concentrations in the sediment pore water and the POC content of the sediment (Fig. F4).

No systematic variation of POC, PN, C/N,  $\delta^{13}\text{C}$ -POC, and  $\delta^{15}\text{N}$ -PN with depth was observed (Fig. F5), with the exception of a correspondence between POC and PN depth profiles. The POC content of sediment samples from Site U1363 ranged from 47 to 391  $\mu\text{mol-C/g}$  (0.06–0.47 wt%), whereas PN ranged from 4.1 to 32.9  $\mu\text{mol-N/g}$  (0.006–0.044 wt%), which were significantly lower than those in rivers and continental-shelf deposits on the Washington Coast (POC = ~3 wt%; PN = ~0.3 wt%) (Keil and Fogel, 2001). The low POC and PN contents suggested that degradation of particulate organic matter had occurred or an accumulation of inorganic material diluted the POC and PN content. POC- $\delta^{13}\text{C}$  values from Site U1363 sediment samples ranged from -25.3‰ to -22.5‰ (Table T2; Fig. F5). For comparison, the organic carbon isotopic composition of fresh marine plankton were measured at approximately -20.5‰ and terrestrial debris at -26‰ (Keil and Fogel, 2001). The similarity of POC and PN profiles resulted in relatively low variation in C/N ratios ( $12 \pm 2$ ;  $n = 54$ ) (Figs. F6, F7), which were slightly higher than the Redfield ratio (~6; Redfield, 1934) but significantly lower than

terrestrial vascular plants (>20) (Meyers, 1994; Keil and Fogel, 2001). POC- $\delta^{13}\text{C}$  values and C/N ratios of Site U1363 sediments suggested that the sediments at Site U1363 were likely a mixture of degraded plankton biomass and terrestrial debris. Some of the low POC and PN and high C/N ratios corresponded to sandy intervals, an indication of the influence of sedimentary composition by turbidites (Fig. F5).

## Acknowledgments

We thank the captain, crew, and Expedition 327 Shipboard Scientists on board the R/V *JOIDES Resolution*. Samples, shipboard pore water alkalinity, and sulfate data were provided by the Integrated Ocean Drilling Program (IODP). We thank Geoff Wheat and Samuel Hulme for extracting sediment pore water for this study, Joseph Lichwa at the Water Resources Research Center at the University of Hawaii for DOC analysis, and Elizabeth Gier at the Biogeochemical Stable Isotope Facility at the University of Hawaii for sediment composition analysis. Funding was provided by an IODP Expedition 327 participation grant (T327A4) and a Center for Dark Energy Biosphere Investigations (C-DEBI) grant to J.P. Cowen, both of which are part of National Science Foundation (NSF)-sponsored programs. This is SOEST contribution Number 9243 and C-DEBI contribution Number 236.

Initial receipt: 11 July 2014

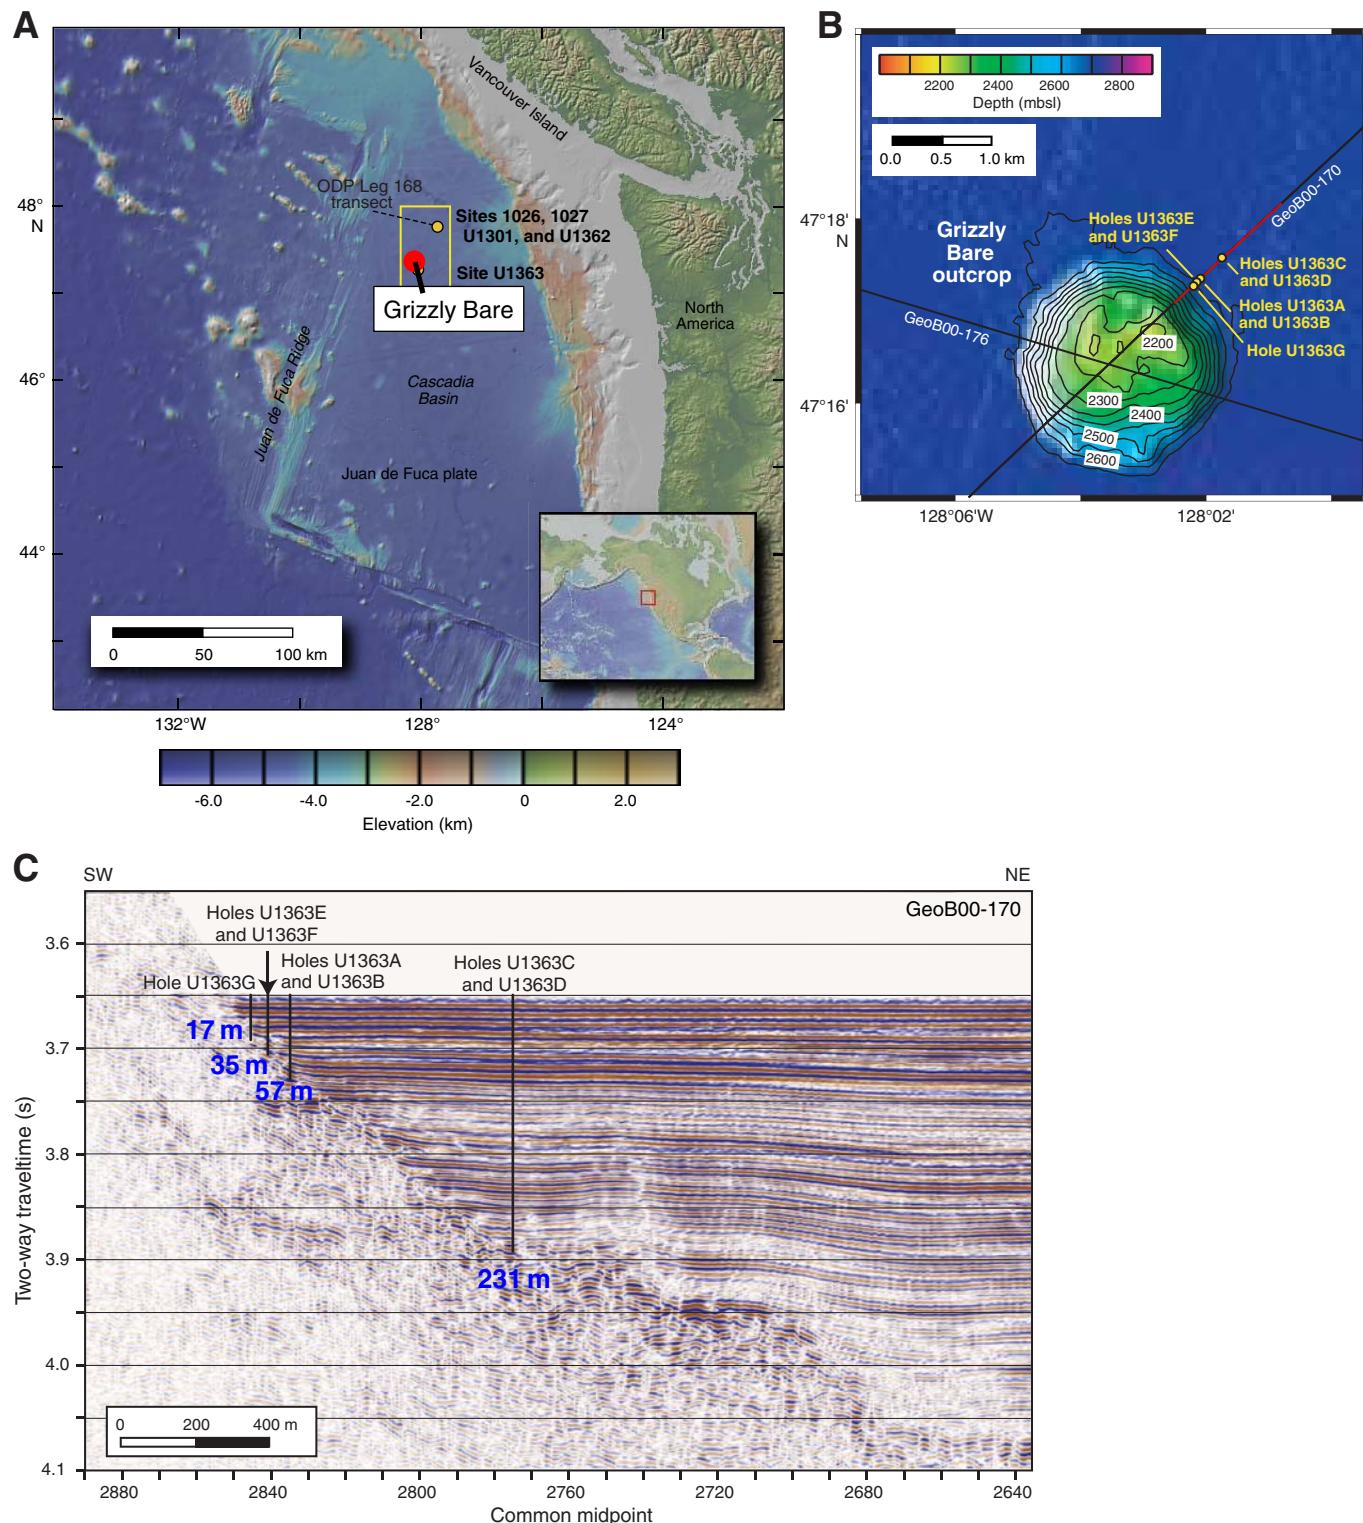

Acceptance: 9 January 2015

Publication: 13 April 2015

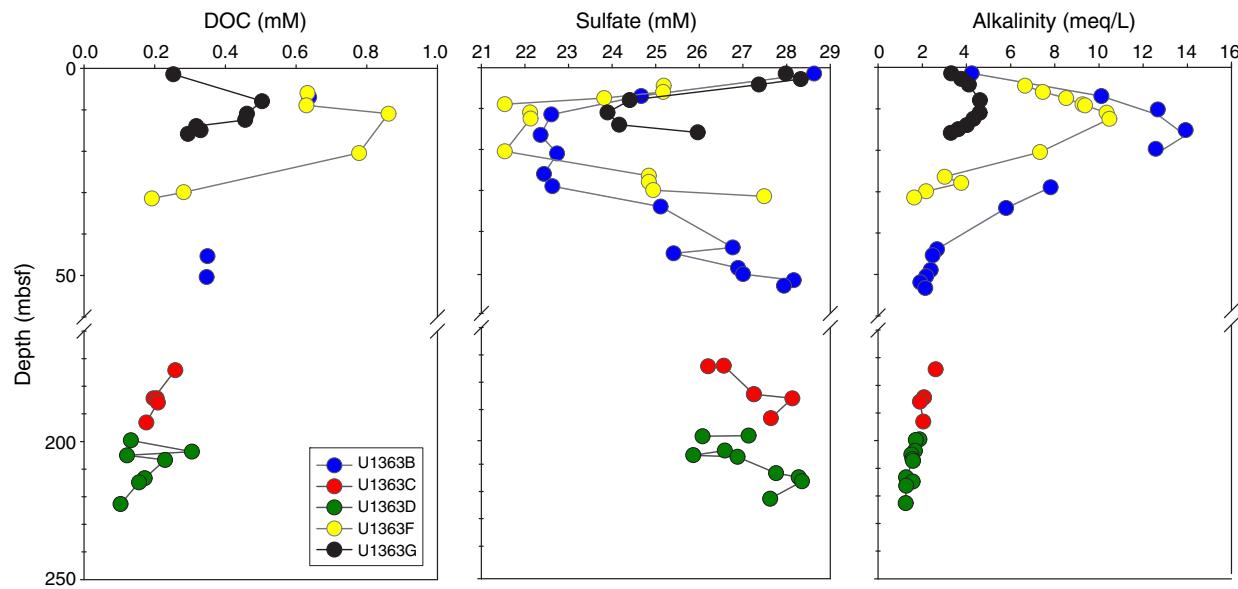

MS 327-202

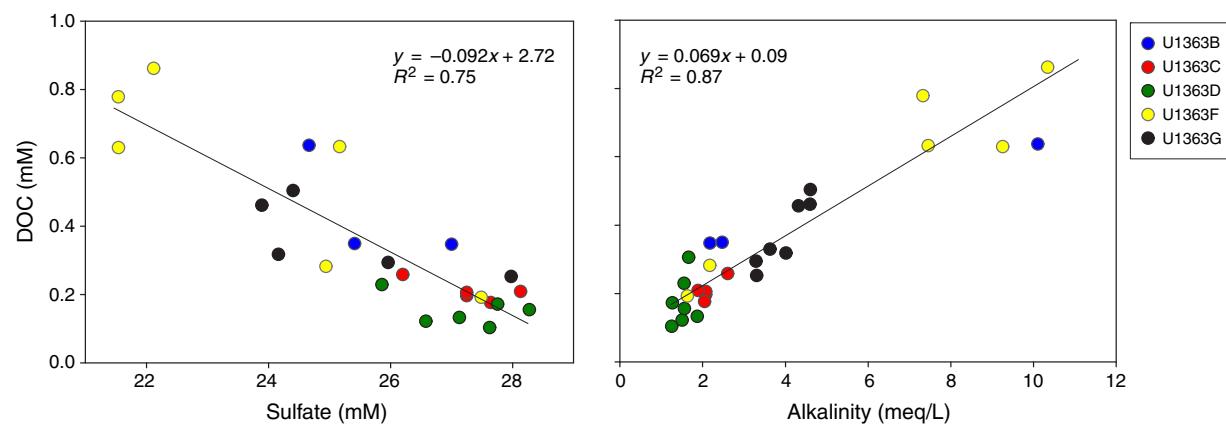

**Figure F1.** A. Location of Grizzly Bare outcrop relative to the US continent. B. Bathymetric map of Site U1363. C. Reflection seismic profile across Holes U1363A–U1363G, showing sediment thickness increasing with distance from Grizzly Bare outcrop. The corresponding basement depths in Holes U1363G, U1363F, U1363B, and U1363C/D are 17, 35, 57, and 231 mbsf, respectively.

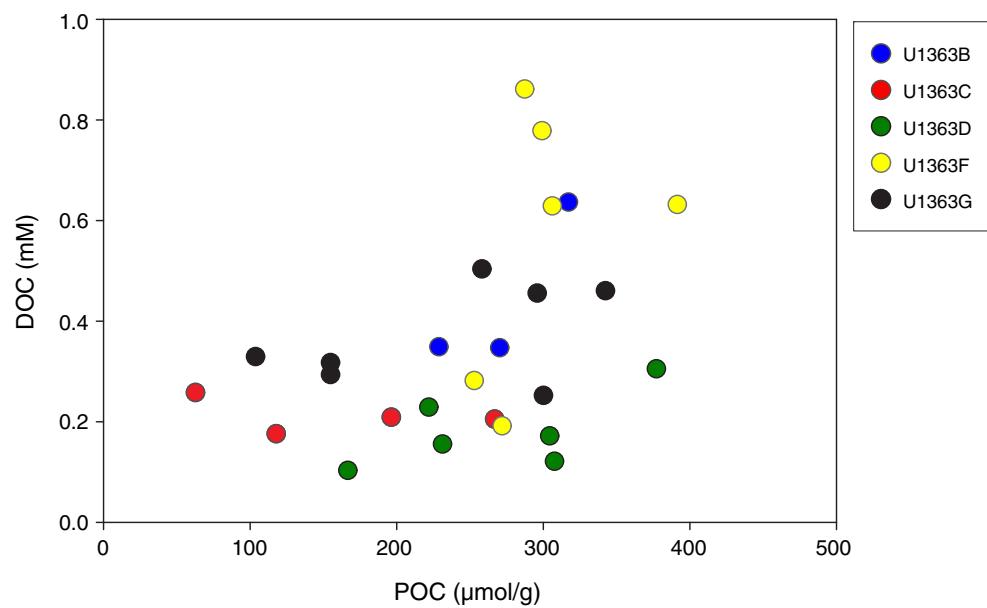

**Figure F2.** Dissolved organic carbon (DOC), sulfate, and alkalinity in pore water from retrieved sediment cores, Site U1363. All holes were sampled to within a few meters of the sediment/basement interface. Only the deepest 50 m of Holes U1363C and U1363D were cored. Sulfate and alkalinity data are from the “[Site U1363](#)” chapter (Expedition 327 Scientists, 2011b).

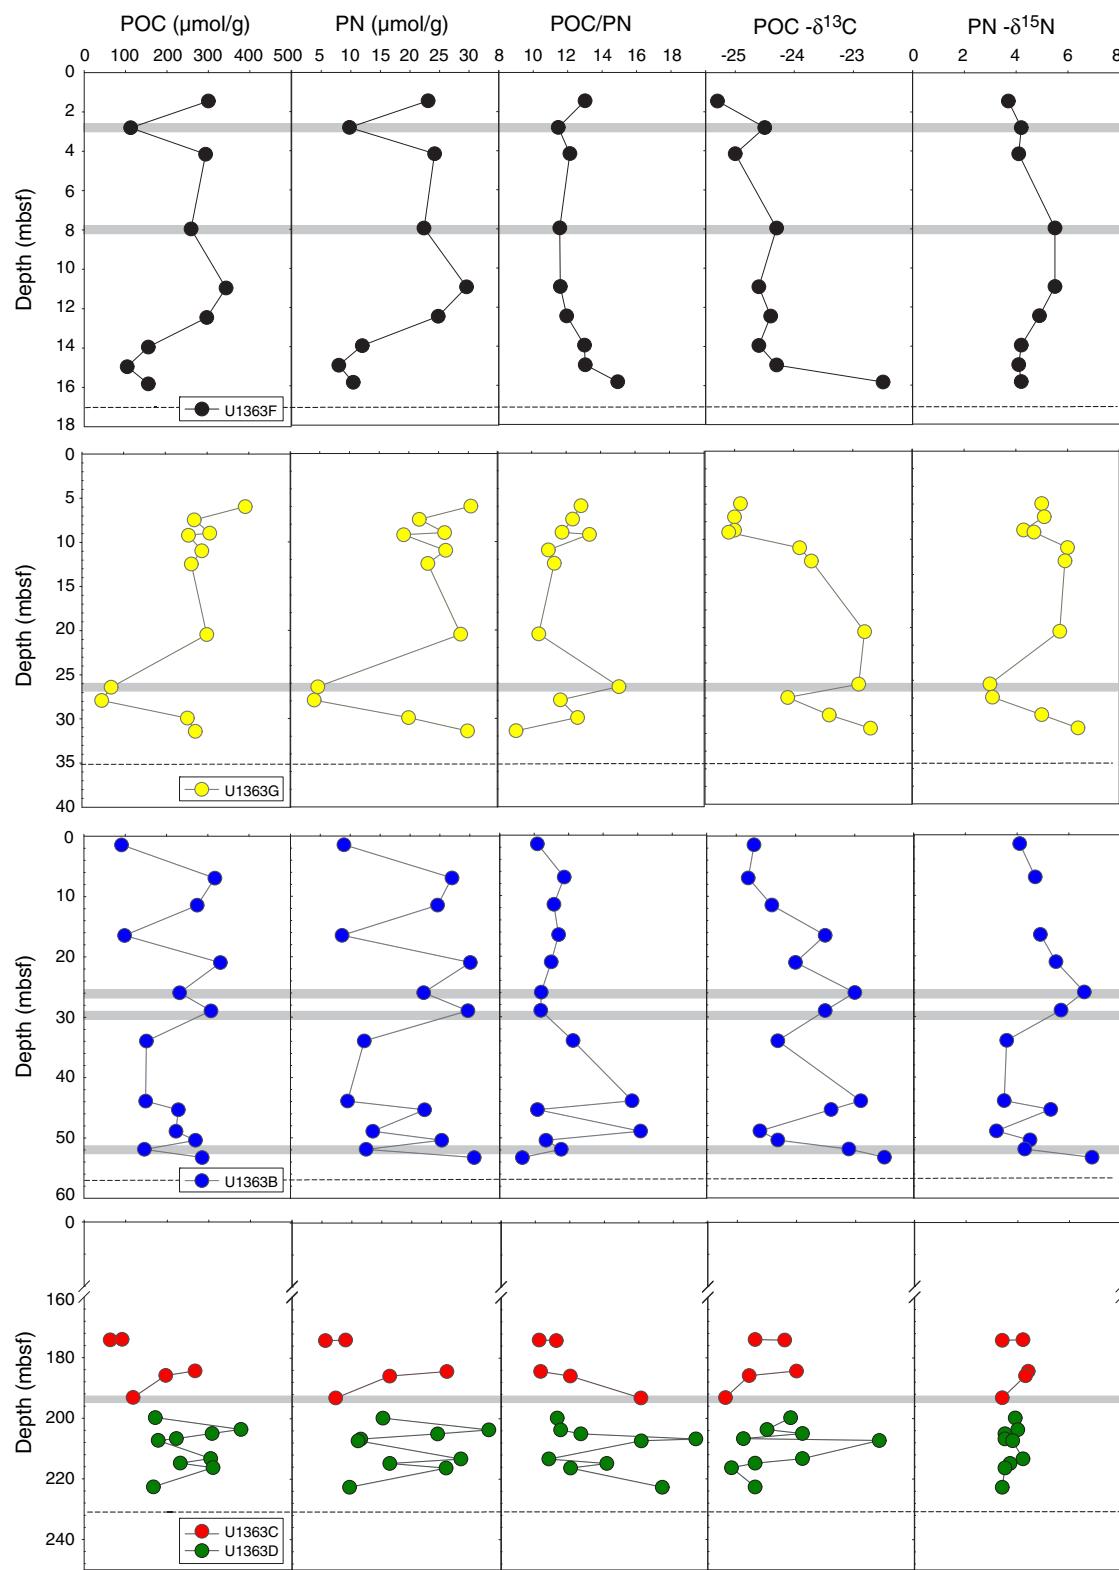

**Figure F3.** Relationship between concentrations of dissolved organic carbon (DOC) and sulfate or alkalinity in pore water from retrieved sediment cores, Site U1363.

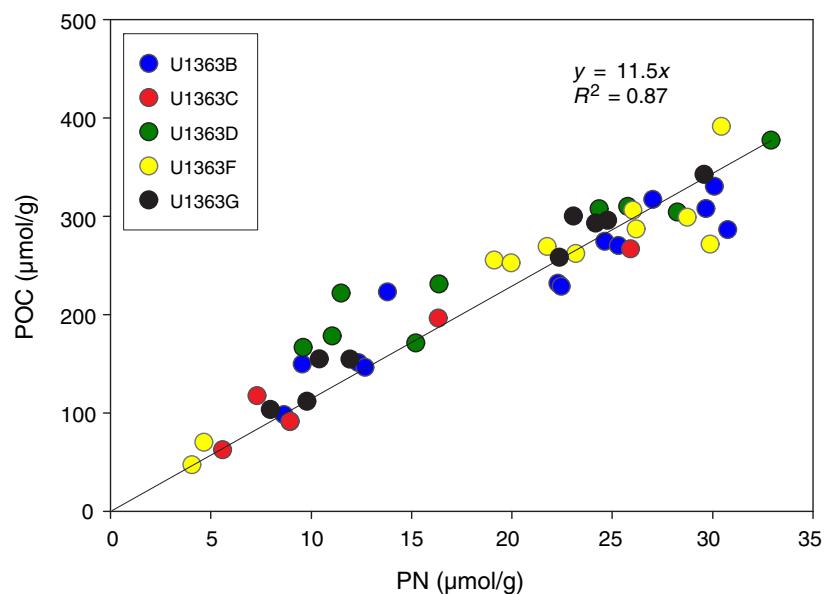

**Figure F4.** Plot of particulate organic carbon (POC) vs. dissolved organic carbon (DOC) concentrations, Site U1363.

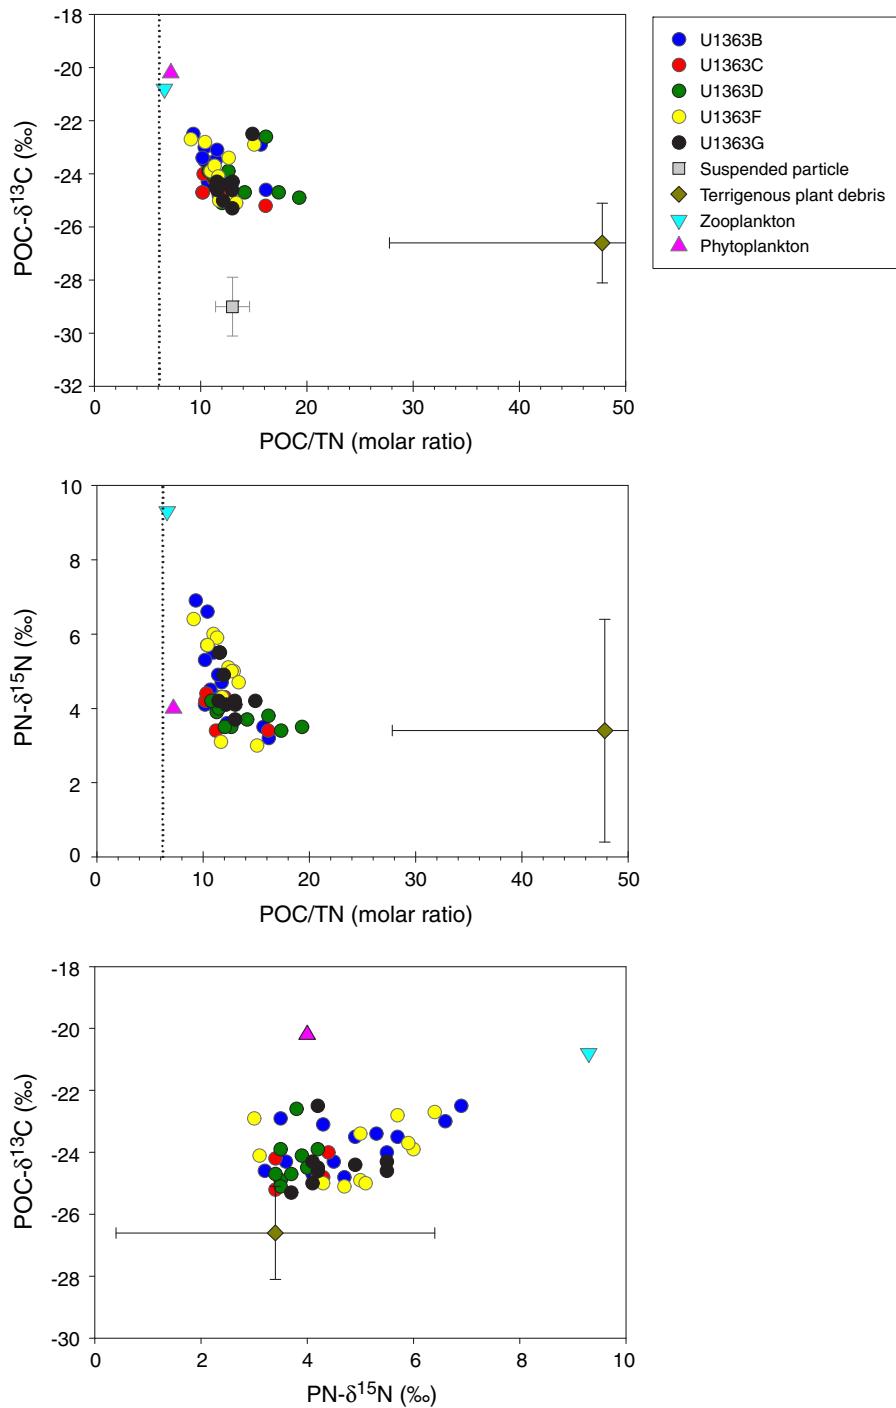

**Figure F5.** Particulate organic carbon (POC) and particulate nitrogen (PN) concentrations, POC/TN molar ratio, carbon isotopic compositions of POC, and nitrogen isotopic compositions of PN in whole sediments, Site U1363. Black dashed lines = depths of sediment/basement interface, gray horizontal lines = sandy events (i.e., major turbidites; see also the “Site U1363” chapter [Expedition 327 Scientists, 2011b]).

**Figure F6.** Plot of particulate organic carbon (POC) vs. total particulate nitrogen (PN) concentrations, Site U1363. Black line = least square regression line of all data points.

**Figure F7.** Relationships between the carbon isotopic composition of particulate organic carbon (POC), nitrogen isotopic composition of total particulate nitrogen (PN), and the POC/TN molar ratio in sediment samples, Site U1363. Suspended particle data are from seawater collected from a water column depth of ~2600 m above Site U1362 located ~50 km northeast of Site U1363 (H.-T. Lin et al., unpubl. data, 2011). Data from plant debris, zooplankton, and phytoplankton are from Keil and Fogel (2001). Black dashed line = Redfield ratio.

**Table T1.** Borehole locations, Site U1363.

Hole	Latitude	Longitude	Depth to basement (mbsf)
327-			
U1363B	47°17.3518'N	128°2.1060'W	57.0
U1363C	47°17.5759'N	128°1.7641'W	NA
U1363D	47°17.5724'N	128°1.7599'W	231.2
U1363F	47°17.3261'N	128°2.1374'W	35.0
U1363G	47°17.3118'N	128°2.1698'W	17.0

NA = not available.

**Table T2.** Pore water analyses results, Site U1363. (Continued on next page.)

Core, section, interval (cm)	Depth average (mbsf)	TDC (mM)	DOC (mM)	DIC (mM)	Acid-fumed PN (%)	POC (%)	Acid-fumed PN ( $\mu\text{mol/g}$ )	POC ( $\mu\text{mol/g}$ )	Acid-fumed PN- $\delta^{15}\text{N}$ (‰)	POC- $\delta^{13}\text{C}$ (‰)	C/N	PN (%)	PC (%)	PN- $\delta^{15}\text{N}$ (‰)	PC- $\delta^{13}\text{C}$ (‰)	PIC (%)	PIC- $\delta^{13}\text{C}$ (‰)
