Abstract

We performed grain size analyses of late Cenozoic hemipelagic mud samples from Holes C0011C and C0011D recovered during Integrated Ocean Drilling Program Expedition 333 (December 2010–January 2011). Hemipelagic mud grains are coarsest in the uppermost 94 m interval; the median diameter is $\sim 7.2 \phi$, although frequency distributions in the interval from 42 to 94 meters below seafloor (mbsf) are exceptionally broadened and flattened relative to the other horizons. Grain size fines downhole with fluctuations in the interval between 94 and 165 mbsf, where median grain size diameter fines downcore from 7 to 8 ϕ . Hemipelagic mud grains are finest in the interval from 165 to 380 mbsf. In this interval, median grain size diameter is consistently $\sim 8 \phi$, although coarsening excursions are present between 214 and 254 mbsf and between 351 and 363 mbsf.

Introduction

The purpose of this study is to provide information about grain sizes of hemipelagic mud in Holes C0011C and C0011D. Grain size distribution is one of the most important properties of sediment and is fundamental data used in studies of many fields.

Grain size distribution provides information about the origin and formative processes of sediment, including provenance, depositional environment, type and intensity of transport mechanisms, and depositional processes (e.g., Visher, 1969; McLaren, 1981; McLaren and Bowles, 1985; Rea and Hovan, 1995; Holz et al., 2004). Therefore, grain size distribution can be a useful proxy in paleoenvironmental studies, especially when combined with other proxies.

Furthermore, physical properties of mud or mudstone are strongly influenced by grain size (Aplin and Macquaker, 2011). Hence, grain size distribution of the sediment deposited on the Philippine Sea plate at the Nankai Trough in Holes C0011C and C0011D will be an important data set when interpreting the downhole variation of several physical properties and the subsequent evolution of these properties during subduction (see the “Site C0011” chapter [Expedition 333 Scientists, 2012]).

Methods and materials

Materials

During Expedition 333, an ocean-floor sediment succession, mostly hemipelagic mud with intercalated ash layers, was sampled from the surface to 379.93 meters below seafloor (mbsf). A total of 277 samples (~10 mL, covering a depth interval of 2 cm) were collected from almost every 150 cm core section. Sand and volcanic ash layers were avoided during sampling; however, a few samples accidentally contain a significant amount of ash. A total of 276 samples were analyzed in this study. The average depth interval between samples is 1.38 m.

Sample preparation

About 50 mg of each sediment sample, which was not dried or crushed, was soaked with 12 mL of 5.5 g/L sodium hexametaphosphate dispersant for >24 h and then was sonicated and well dispersed by hand shaking. Stiff lumps were gently crushed with a thin wood stick within the dispersant. To check for errors originating from nonhomogeneity of the samples, three aliquots using a different part of each sample block were made for 27 samples, selected from each consecutive 10 samples (Table T1).

Grain size analysis

Grain size analysis was carried out using a Malvern Mastersizer 2000 laser diffractometer with an automated sample dispersion unit (Hydro 2000S) installed at the Kochi Core Center (Japan). Principles of the instrument are described in Sperazza et al. (2004). We adopted the procedure and analytical setting proposed by Sperazza et al. (2004) with some modification. In this study, samples dispersed in advance were poured into the dispersion unit, with pump speed and intensity of sonication set to 2000 rpm and 20%, respectively. The input amount of the samples was controlled so that obscuration fell within the 15%–20% range. The grain reflectance index and dispersant were set to 1.555 and 1.33, respectively. Particle absorption was set to 1. Each measurement run was set for 12 s, or 12,000 snaps, and repeated five times. Grain size analyses reported in this paper are the fifth result of the repetition series. Prior to accepting an analysis, we visually inspected the output from each of the five runs for consistency.

Results were compiled with Malvern's Mastersizer 2000 software as the volume frequency of 100 size

classes. The boundaries between classes are set as a geometric series from 0.02 to 2000 μm . For convenience, we used the phi (ϕ) scale in the following text, table, and figures. The grain size unit ϕ is derived as follows:

$$\phi = -\log_2(d/d_0),$$

where d (in millimeters) is the diameter of a particle and d_0 is a reference diameter equal to 1 mm.

Results

Results are shown in Figures F1 and F2 and in Table T1. Raw data of frequency distribution is provided in GRAINSIZ in “Supplementary material.”

Errors derived from nonhomogeneity of samples were mostly $<0.2 \phi$, except for mode diameter, in terms of standard deviation of each representative value derived from measurements of three different aliquots from each of 27 selected samples (Fig. F3). Correlation of standard deviation to 10-percentile and median diameter is a nonzero value by >0.99 probability, and that to mean diameter is >0.98 probability (Fig. F4). Smaller diameters tend to show smaller standard deviation values. Thus, a difference of ~0.2 ϕ in median diameter between different samples can be regarded significant if the median diameter is $<7 \phi$.

Hemipelagic mud grains are coarsest in the uppermost 94 m interval, with median diameters of $\sim 7.2 \phi$. However, the 42–94 mbsf interval is characterized by a broadened grain size frequency distribution. In contrast, median and 10-percentile diameters differ little from the uppermost 42 m interval; 90-percentile diameter is obviously coarser between 42 and 94 mbsf than in the uppermost interval. Frequency distributions are also flattened because of the low frequency of modal grain size (Fig. F1).

Grain size generally fines downcore with fluctuations in the 94 to 165 mbsf interval. Median and 90-percentile diameters fine from 7 to 8 ϕ and from 5 to 6 ϕ , respectively, whereas 10-percentile diameter fines slightly from 9.6 to 10 ϕ (Fig. F2A).

Hemipelagic mud grains are finest from 165 to 380 mbsf (Figs. F1, F2). In this interval, grain size shows narrow, sharp frequency distribution, and median diameter is almost steady at $\sim 8 \phi$. A few excursions were observed between 254 and 214 mbsf, where median diameter coarsens to 6.5 ϕ , and between 351 and 363 mbsf, where median diameter coarsens to 5.3 ϕ .

Acknowledgments

This research used samples and data provided by the Integrated Ocean Drilling Program (IODP). Funding was provided by Japan Drilling Earth Science Consortium and Center for Deep Earth Exploration.
